

AFFINE LINKING NUMBERS AND CAUSALITY RELATIONS FOR WAVE FRONTS

VLADIMIR V. CHERNOV (TCHERNOV) AND YULI B. RUDYAK

ABSTRACT. Two wave fronts W_1 and W_2 that originated at some points of the manifold M^n are said to be causally related if one of them passed through the origin of the other before the other appeared. We define the causality relation invariant $CR(W_1, W_2)$ to be the algebraic number of times the earlier born front passed through the origin of the other front before the other front appeared. Clearly, if $CR(W_1, W_2) \neq 0$, then W_1 and W_2 are causally related. If $CR(W_1, W_2) = 0$, then we generally can not make any conclusion about fronts being causally related. However we show that for front propagation given by a complete Riemannian metric of non- positive sectional curvature, $CR(W_1, W_2) \neq 0$ if and only if the two fronts are causally related. The models where the law of propagation is given by a metric of constant sectional curvature are the famous Friedmann Cosmology models.

The classical linking number lk is a $\mathbb{Z}$ -valued invariant of two zero homologous submanifolds. We construct the affine linking number generalization AL of the lk invariant to the case of linked $(n-1)$ -spheres in the total space of the unit sphere tangent bundle $(STM)^{2n-1} \rightarrow M^n$. For all M , except of odd-dimensional rational homology spheres, AL allows one to calculate the value of $CR(W_1, W_2)$ from the picture of the two wave fronts at a certain moment. This calculation is done without the knowledge of the front propagation law and of their points and times of birth. Moreover, in fact we even do not need to know the topology of M outside of a part $\overline{M}$ of M such that W_1 and W_2 are null-homotopic in $\overline{M}$.

INTRODUCTION

In this paper the word “smooth” means C^∞ . Throughout this paper M is a smooth connected oriented Riemannian n -dimensional manifold (not necessarily compact). In our paper the wave fronts on M are assumed to be parametrized by smooth mappings of manifolds. They are not assumed to be immersed and are allowed to have various singularities including degenerations of the differential. The popular case of wave fronts being projections to M of Legendrian mappings of N^{n-1} (parameterizing the fronts) to the unit cotangent bundle $(ST^*M)^{2n-1} \subset T^*M = TM$ of M is easily obtained from our paper as a particular, though a very important case. (The front stays smooth,

Key words and phrases. linking numbers, wave fronts, causality, degree of a mapping, Weingarten map.

though not immersed, at the cusp points and other singularities of the projections to M of Legendrian mappings $N^{m-1} \rightarrow (ST^*M)^{2n-1}$.)

Let W_1 and W_2 be two wave fronts which are propagating in M . (Generally, we assume that the fronts have different propagation laws.) We define a *dangerous intersection* between the fronts $W_1(t)$ and $W_2(t)$ at some moment of time t to be a point x where the fronts intersect and have the same direction of propagation (see Section 1 for the precise definition).

A passage of the front $W_1(t)$ through the birth point of the front W_2 at the moment of time t before the front W_2 originated is called the *baby- intersection*.

It turns out that we can associate to each dangerous intersection as well as to each baby-intersection a sign (i.e. a number ± 1). The sum of the signs up to a moment t is called a *causality relation invariant* and is denoted by $\text{CR}(W_1(t), W_2(t))$.

In particular, assume that there are no dangerous intersections of $W_1(t)$ and $W_2(t)$ for all t . (Many such examples are constructed in Section 1 and, for example, light and sound wave fronts have this property.) Then the causality relation invariant tells us the algebraic number of times the earlier-born wave front passed through the birth point of the other front before the other front originated.

Two wave fronts W_1 and W_2 that originated at some points of the manifold M^m are said to be *causally related* if one of them passed through the origin of the other before the other appeared. Clearly, if $\text{CR}(W_1, W_2) \neq 0$ and no dangerous intersections occurred during the propagation, then W_1 and W_2 are causally related.

If $\text{CR}(W_1, W_2) = 0$, then we generally can not make any conclusion about fronts being causally related. However we show that in case of front propagation given by a complete Riemannian metric of non-positive sectional curvature, $\text{CR}(W_1, W_2) \neq 0$ if and only if the two fronts are causally related, see 2.5. The models where the law of propagation is given by a metric of constant sectional curvature are the famous Friedmann Cosmology models.

We are interested in reconstructing the value $\text{CR}(W_1(t), W_2(t))$ from the current shape of the wave fronts only, without the knowledge of the propagation laws, of the birth-points of the fronts, of the topology of M etc.

It turns out that, having the current picture only, we can evaluate $\text{CR}(W_1(t), W_2(t)) \in \mathbb{Z}$ modulo a certain $m \in \mathbb{Z}$ that depends on M . This m is zero if M is not an odd-dimensional rational homology sphere, see Proposition 3.8, and when $m = 0$ we can completely reconstruct the value of $\text{CR}(W_1(t), W_2(t)) \in \mathbb{Z}$. Furthermore, for M

odd-dimensional this m is divisible by the order of $\pi_1(M)$, see Proposition 3.8. In particular, if $\pi_1(M)$ is infinite then $m = 0$, i.e. we can completely evaluate CR from the current picture. The really bad case $m = 1$ (when we can not say anything about CR) appears only when M is an odd-dimensional homotopy sphere. In particular, for Friedmann cosmology models based on a Riemannian metric of non-positive sectional curvature our methods allow one to detect precisely whether two wave fronts are causally related or not from the current picture of the wave fronts only, see 4.10.

To evaluate CR modulo m , we introduce an invariant $AL \in \mathbb{Z}/m\mathbb{Z}$, the so-called affine linking invariant, which depends on the current picture only. Then we notice that CR and AL are congruent modulo m . Here the biggest technical difficulty appears, since in order to define AL we must define the “linking number” for two spheres that are non-homologous to zero. (This affine linking number can be shown to be a particular case of a very general affine linking invariant discussed in our later work [10]. However, results of this paper are independent from the results of [10] and are not corollaries of our results obtained later.)

This theory has the following physical interpretation. Let $\overline{M}$ be the part of the manifold (the universe) M such that $\overline{M}$ contains the current picture of wave fronts W_1, W_2 , and W_1, W_2 are contractible in $\overline{M}$.

We transform the wave fronts via certain allowable moves to trivial fronts, i.e. small spherical fronts with the canonical orientation and coorientation, located far away from each other. The allowable moves should be thought of as generalized Reidemeister moves: they are the passages through generic singularities (in both directions) of wave fronts and dangerous intersection moves. We count the change of the invariant CR that occurs in the process of this formal deformation, and it turns out that this change is congruent modulo m with the (unknown!) value $CR(W_1, W_2)$ of the current picture. In particular, as we have already mentioned, if M is not an odd-dimensional rational homology sphere or if $\pi_1(M)$ is infinite, then we can completely compute CR from the current picture, without any knowledge of the propagations, moments and points of birth of the fronts, and topology of M outside of $\overline{M}$.

The following observation seems to be interesting. Suppose that we have two pictures of two pairs of fronts (W_1, W_2) and (W'_1, W'_2) made at two unknown moments of time t_0 and t_1 . (We assume that both pairs are free of dangerous intersection points.) Assume that we know that the propagation laws for the two fronts are such that the dangerous intersection points cannot appear during the propagation and

that $\text{CR}(W_1(t_0), W_2(t_0))$ and $\text{CR}(W'_1(t_1), W'_2(t_1))$ are not comparable modulo m . Then we can conclude that the pairs $(W_1(t_0), W_2(t_0))$ and $(W'_1(t_1), W'_2(t_1))$ of wave fronts are not the pictures of the same pair of fronts taken at different moments of time.

Note that in these calculations we disregard the dangerous self-intersections of wave fronts. (In a sense this is similar to the theory of link homotopy where different components of links are not allowed to intersect through possible deformations, but self-intersections are allowed.) The study of self-intersections of fronts on surfaces was initiated by the ground breaking work of Arnold [4], see also [1, 2, 11, 15, 16, 18, 19, 25, 26, 6, 7, 9, 30]. The methods developed in this paper allow us to calculate the algebraic number of dangerous self-intersection points that arise under the propagation of fronts on manifolds of arbitrary dimensions, we do it in a next paper.

The following physical speculations related to the CR invariant seem to be possible. Assume that the space-time is topologically a product $M^n \times \mathbb{R}$, and that the observable universe $\overline{M}$ is so big that we are not able to see the current picture of wave fronts (due to the finiteness of the speed of light). The propagating fronts define the mapping of the cones C_1, C_2 (over the sphere S^{n-1} parameterizing the fronts at every moment of time) into $M \times \mathbb{R}$. Let $\text{sec} : \overline{M} \rightarrow \overline{M} \times \mathbb{R}$ be a section of the projection $p_{\overline{M}} : \overline{M} \times \mathbb{R} \rightarrow \overline{M}$, and let $\overline{W}_i = C_i \cap \text{sec}(\overline{M}), i = 1, 2$. Assume that the law of propagation is such that dangerous intersections do not occur. Then, similarly to the above, we can restore the number of baby-intersections from the picture of images of $\overline{W}_i$ under the projection $p_{\overline{M}}$. The section sec can be thought of as the picture of the universe that we see as the light from the points of $\overline{M}$ reaches the observer, and thus $\overline{W}_i$ can be regarded as the picture of fronts that we actually see.

Low [20, 21, 22] attacked a similar problem for $M = \mathbb{R}^3$, where he considered a linking invariant for linked cones C_1, C_2 as above. In this case the linking numbers can be constructed directly via the approach of Tabachnikov [30], because $\mathbb{R}^3$ has the topological end. (Some very interesting results relating causality for fronts on $\mathbb{R}^2$ and linking were obtained recently by Nataro and Todd [23].)

The paper is organized as follows. In Section 1 we discuss some preliminary information, in Section 2 we define the invariant CR, in Section 3 we prove homotopy theoretical results which we use in order to define the invariant AL, in Section 4 we define the invariant AL and state the relation between CR and AL, in Section 5 we treat the case of propagation with respect to a certain Riemannian metric, in Section 6 we give some examples and applications.

1. PRELIMINARIES: PROPAGATION LAWS, PROPAGATIONS AND DANGEROUS INTERSECTIONS

We denote by $p_T : TM \rightarrow M$ the tangent bundle over M . Let $s : M \rightarrow TM$ be the zero section of the tangent bundle. We set $\overline{TM} = TM \setminus s(M)$. The multiplicative group $\mathbb{R}^+$ of positive real numbers acts fiberwise on $TM \setminus s(M)$ by multiplication, and we set

$$STM = (TM \setminus s(M))/\mathbb{R}^+.$$

Let $\bar{p} : \overline{TM} \rightarrow STM$ be the quotient map. Clearly, the projection $p_T : TM \rightarrow M$ yields the commutative diagram

$$\begin{array}{ccccc} TM & \xrightarrow{\supset} & \overline{TM} & \xrightarrow{\bar{p}} & STM \\ p_T \downarrow & & \downarrow & & \downarrow \text{pr} \\ M & \xlongequal{\quad} & M & \xlongequal{\quad} & M \end{array}$$

It is easy to see that $\text{pr} : STM \rightarrow M$ is a locally trivial bundle with the fiber S^{n-1} , we call this bundle the *spherical tangent bundle*.

Given $x \in M^n$, we denote by S_x^{n-1} (or just by S_x) the fiber $\text{pr}^{-1}(x)$ over x of the spherical tangent bundle and by $T_x M$ the tangent space to M at x .

Since M is orientable, the bundle $\text{pr} : STM \rightarrow M$ is also orientable, and in order to orient STM it suffices to orient the fiber S_x^{n-1} . We do it as follows. Choose an orientation preserving chart for M centered at x and let S be a small $(n-1)$ -sphere centered at x . We equip S with the unique orientation o by requiring that the pair $(o, \text{outer normal vector to } S)$ gives us the orientation of M .

Given $s \in S$, the radius-vector from x to s can be regarded as a nonzero tangent vector to M at x , i.e., as a point of S_x^{n-1} . In this way we get a diffeomorphism $\psi : S \rightarrow S_x$ which gives us an orientation of S_x^{n-1} . It is easy to see that this orientation of S_x does not depend of choice of the chart. Now, the pair (the orientation of M , the orientation of S_x) gives us an orientation of STM which we fix forever.

1.1. Definition. We define a *propagation law* on M to be a smooth map

$$L : \overline{TM} \times \mathbb{R} \times \mathbb{R} \rightarrow \overline{TM}$$

(a time-dependent flow on $\overline{TM}$). Here $L(\mathbf{u}, s, t) \in \overline{TM}$ should be thought of as the point that corresponds to the position and the velocity vector at moment $s+t$ of a perturbation whose position and the velocity vector at moment s was $\mathbf{u}$. (We assume that a velocity of movement of a perturbation is either zero all the time or nonzero all the time.)

Furthermore we assume that $L(\mathbf{u}, s, t)$ satisfies the following natural conditions:

- a:** $L(\mathbf{u}, s, 0) = \mathbf{u}$ for all $\mathbf{u} \in \overline{TM}$;
- b:** $\forall s, t \in \mathbb{R}$ the map $L_{s,t} : \overline{TM} \rightarrow \overline{TM}$ defined as $L_{s,t}(\mathbf{u}) = L(\mathbf{u}, s, t)$ is a diffeomorphism;
- c:** $L(\mathbf{u}, s, t_1 + t_2) = L(L(\mathbf{u}, s, t_1), s + t_1, t_2)$, $\forall s, t_1, t_2 \in \mathbb{R}$;
- d:** $\forall \mathbf{u} \in \overline{TM}$ and $\forall s_0, t_0 \in \mathbb{R}$

$$\left. \frac{d}{dt} p_T(L(\mathbf{u}, s_0, t)) \right|_{t=t_0} = L(\mathbf{u}, s_0, t_0).$$

1.2. Definition. A *propagation* is a quadruple $P = (L, x, T, V)$ where L is a propagation law, $x \in M, T \in \mathbb{R}$ and $V : S_x^{n-1} \rightarrow (T_x M \setminus s(x))$ is a smooth section of the $\mathbb{R}^+$ -bundle $(T_x M \setminus s(x)) \rightarrow S_x^{n-1}$. We fix an orientation preserving diffeomorphism $S^{n-1} \rightarrow S_x^{n-1}$ and further in the text regard V as a mapping $V : S^{n-1} \rightarrow (T_x M \setminus s(x))$.

A propagation $P = (L, x, T, V)$ produces a wave front $W(t) : S^{n-1} \rightarrow M, t \geq T$, as follows. Informally speaking, we assume that at a moment of time T something happens at a point $x \in M$ and the perturbation caused by this event starts to radiate from the point x in all the directions according to a propagation law L with the initial velocities of propagation in $T_x M$ described by V . Formally, for $t \geq T$ we define the front $W(t)$ to be the mapping

$$W(t) := p_T(L(V, T, t - T)) : S^{n-1} \rightarrow M.$$

We put $\overline{W}(t) = L(V, T, t - T)$ and $\widetilde{W}(t) = \overline{p} \circ \overline{W}(t)$. In this case we also say that the wave front has *originated from the event* (x, T) . Initially a front of an event is a smooth embedded sphere (because of 1.1(d)), but generically it soon acquires double points, folds, cusps, swallow tails, and other complicated singularities. Generally, singular values of the front form a codimension two subset of M .

We denote by $\varepsilon_x : S^{n-1} \rightarrow STM$ any map of the form

$$(1.1) \quad S^{n-1} \xrightarrow{h} S_x^{n-1} \subset STM$$

where h is a map of degree 1. Clearly, the homotopy class of ε_x is well-defined and does not depend on x .

Let $\mathcal{S}$ be the space of smooth maps $S^{n-1} \rightarrow STM$ that are homotopic to a map ε_x as in (1.1). Then $\mathcal{S} \times \mathcal{S}$ is the space of ordered pairs (f_1, f_2) with $f_i \in \mathcal{S}$.

Put Σ to be the discriminant in $\mathcal{S} \times \mathcal{S}$, i.e. the subspace that consists of pairs (f_1, f_2) such that there exist $y_1, y_2 \in S^{n-1}$ with $f_1(y_1) = f_2(y_2)$.

(We do not include into Σ the maps that are singular in the common sense but do not have double points between the two different spheres.)

1.3. Definition. We define Σ_0 to be a subset (stratum) of Σ consisting of all the pairs (f_1, f_2) such that there exists precisely one pair of points $y_1, y_2 \in S^{n-1}$ such that:

- a:** $f_1(y_1) = f_2(y_2)$. And moreover this pair of points is such that:
- b:** y_i is a regular point of $f_i, i = 1, 2$;
- c:** $(df_1)(T_{y_1}) \cap (df_2)(T_{y_2}) = 0$. Here df_i is the differential of f_i and T_{y_i} is the tangent space to S^{n-1} at y_i .

1.4. Construction. Let $\rho : (a, b) \rightarrow \mathcal{S} \times \mathcal{S}$ be a path which intersects Σ_0 in a point $\rho(t_0)$. We also assume that

$$\rho(t_0 - \delta, t_0 + \delta) \cap \Sigma_0 = \rho(t_0)$$

for δ small enough. We construct a vector $\mathbf{v} = \mathbf{v}(\rho, t_0, \delta)$ as follows. We regard $\rho(t_0)$ as a pair $(f_1, f_2) \in \mathcal{S} \times \mathcal{S}$ and consider the points y_1, y_2 as in 1.3. Set $z = f_1(y_1) = f_2(y_2)$. Choose a small $\delta > 0$ and regard $\rho(t_0 + \delta)$ as a pair $(g_1, g_2) \in \mathcal{S} \times \mathcal{S}$. Set $z_i = g_i(y_i), i = 1, 2$. Take a chart for STM that contains z and $z_i, i = 1, 2$ and set

$$\mathbf{v}(\rho, t_0, \delta) := \overrightarrow{zz_1} - \overrightarrow{zz_2} \in T_z STM.$$

1.5. Definition. Let $\rho : (a, b) \rightarrow \mathcal{S} \times \mathcal{S}$ be a path as in 1.4. We say that ρ intersects Σ_0 transversally for $t = t_0$ if there exists $\delta_0 > 0$ such that

$$\mathbf{v}(\rho, t_0, \delta) \notin (df_1)(T_{y_1} S^{n-1}) \oplus (df_2)(T_{y_2} S^{n-1}) \subset T_z STM$$

for all $\delta \in (0, \delta_0)$.

It is easy to see that the concept of transversal intersection does not depend on the choice of the chart.

1.6. Definition. A path $\rho : (a, b) \rightarrow \mathcal{S} \times \mathcal{S}, -\infty \leq a < b \leq \infty$ is said to be *generic* if

- a:** $\rho(a, b) \cap \Sigma = \rho(a, b) \cap \Sigma_0$;
- b:** the set $J = \{t | \rho(t) \cap \Sigma_0 \neq \emptyset\} \subset (a, b)$ is an isolated subset of $\mathbb{R}$;
- c:** the path ρ intersects Σ_0 transversally for all $t \in J$.

As one can expect, every path can be turned into a generic one by a small deformation. We leave a proof to the reader.

Let $P_1 = (L_1, x_1, T_1, V_1)$ and $P_2 = (L_2, x_2, T_2, V_2)$ be two propagations. They define mappings $r_i : \mathbb{R} \rightarrow \mathcal{S}$, $i = 1, 2$ as follows.

$$r_i(t) = \begin{cases} \bar{p} \circ V_i & \text{for } t \leq T_i, \\ \widetilde{W}_i(t) & \text{for } t > T_i. \end{cases}$$

1.7. Definition. A pair of propagations $\{P_1, P_2\}$ is said to be *generic* if the path $r = (r_1, r_2) : \mathbb{R} \rightarrow \mathcal{S} \times \mathcal{S}$ is generic and $r(T_i) \notin \Sigma$, $i = 1, 2$.

1.8. Definition. Let $\{P_1, P_2\}$ be a generic pair of propagations and let $r : \mathbb{R} \rightarrow \mathcal{S} \times \mathcal{S}$ be as above. Then a moment $t \in \mathbb{R}$ such that $r(t) \in \Sigma$ corresponds either to the baby-intersection or to the case where $t > \max(T_1, T_2)$ and there exists $y_1, y_2 \in S^{n-1}$ such that $W_1(t)(y_1) = W_2(t)(y_2) = z$ and $\widetilde{W}_1(t)(y_1) = \widetilde{W}_2(t)(y_2) \in S_z^{n-1}$, i.e. to the case where there is a double point of the two fronts $W_1(t)$ and $W_2(t)$ at which the directions of the propagations of the two fronts coincide. Such a double point of two fronts is called a *point of dangerous intersection*. Notice that we do not exclude situations in which the two fronts are tangent, the so-called *Arnold's dangerous tangencies*, cf. [4].

For many pairs of propagations the dangerous intersection points do not occur. Such pairs of propagations are called *dangerous intersections free*. Now we describe a source of examples of such pairs.

1.9. Source of Examples of propagations without dangerous intersections. Let $L : \overline{TM} \times \mathbb{R} \times \mathbb{R} \rightarrow \overline{TM}$ be a propagation law. Suppose that there exists a section

$$\widetilde{s} : STM \times \mathbb{R} \times \mathbb{R} \rightarrow \overline{TM} \times \mathbb{R} \times \mathbb{R}$$

of the map $\bar{p} \times 1 \times 1$ such that $\text{Im}(\widetilde{s})$ consists of the trajectories of L , i.e. if $(\mathbf{u}, s_0, 0) \in \text{Im}(\widetilde{s})$ for some $\mathbf{u} \in \overline{TM}$ and $s_0 \in \mathbb{R}$, then $L(\mathbf{u}, s_0, t) \in \text{Im}(\widetilde{s})$, for every $t \in \mathbb{R}$.

Let $P_1 = (L, x_1, T_1, V_1)$ and $P_2 = (L, x_2, T_2, V_2)$ be propagations such that $(\text{Im}(V_1), T_1, 0) \subset \text{Im}(\widetilde{s}|_{S_{x_1, T_1, 0}})$, $(\text{Im}(V_2), T_2, 0) \subset \text{Im}(\widetilde{s}|_{S_{x_2, T_2, 0}})$ and $r(T_i) \notin \Sigma$, $i = 1, 2$.

It is easy to see that *the pair (P_1, P_2) is dangerous intersections free*.

1.10. Example. Propagations that are defined by a Riemannian metric. An interesting class of examples comes from the propagation defined by the geodesics of a complete Riemannian metric g on M . In this case $L(\mathbf{u}, s, t)$ is just a point on $\overline{TM}$ that corresponds to a velocity vector at moment $s + t$ of a geodesic curve that had a velocity vector $\mathbf{u}$ at the moment s . Thus the wave front $W(t)$ corresponding to a propagation (L, x, T, V) can be described as $W(t) : S^{m-1} \rightarrow M$ with

$W(t)(y) = \exp_x((t - T)V(y))$, $y \in S^{m-1}$, where $\exp_x : T_x M \rightarrow M$ is the exponent map corresponding to the Riemannian metric g .

It is easy to see that in these examples if $V(S^{m-1})$ is a sphere of some radius r , then at every moment of time the velocity vectors of the points on the wave front are perpendicular to the image of the front. *Thus, in this case the dangerous intersections are precisely the dangerous tangencies.*

Furthermore, if both $\text{Im } V_1$ and $\text{Im } V_2$ are spheres of the same radius r , then the dangerous intersections (= dangerous tangencies) do not occur, since spheres of radius r in all the tangent spaces produce the section $\tilde{s}$ described above.

1.11. Example. Propagation in a non-homogeneous and non-isotropic medium whose structure does not depend on time.

Assume that M is a Riemannian manifold and $\mu : STM \rightarrow \overline{TM}$ is a smooth section of the corresponding $\mathbb{R}^+$ -bundle such that $\text{Im}(\mu|_{S_x})$ bounds a strictly convex domain in $T_x M$ for all $x \in M$. The radius vector from $s(x)$ to $\text{Im}(\mu|_{S_x})$ in the given direction is the velocity vector of the distortion traveling

in the direction. This information allows us to calculate for every smooth curve $\gamma : [t_1, t_2] \rightarrow M$ the total time $\tau(\gamma)$ needed for the distortion to travel along this curve.

Assume $\text{Im}(V_1) \subset \text{Im } \mu$ and $\text{Im}(V_2) \subset \text{Im } \mu$ and that propagation occurs according to the Huygens principle, i.e. distortion travels along the extremal curves of the functional τ on the space of smooth curves on M . *It is clear that here we have a special case of the situation described in 1.9, and so the dangerous intersection points do not occur for such a pair of propagation.* On the other hand, if the propagation happens according to the Huygens principle then at every point $W(t)(x) = z$ the normal vector to the wave front is conjugate with respect to $\mu|_{S_z}$ to the direction of the extremal curve along which the information traveled to this point, Arnold [5]. In particular, in this case the dangerous tangencies do not occur under the wave fronts propagation, since they are the dangerous intersections.

2. THE CAUSALITY RELATION INVARIANT

Recall that the standard sphere S^{n-1} is assumed to be oriented. We say that a tangent frame $\mathfrak{r}$ to S^{n-1} is positive if it gives us the standard orientation of S^{n-1} .

2.1. Definition. Let ρ be a path in $\mathcal{S} \times \mathcal{S}$ that intersects Σ transversally in one point $\rho(t_0) \in \Sigma_0$. We associate a sign $\tilde{\sigma}(\rho, t_0)$ to such a crossing as follows.

We regard $\rho(t_0)$ as a pair $(f_1, f_2) \in \mathcal{S} \times \mathcal{S}$ and consider the points $y_1, y_2 \in S^{n-1}$ such that $f_1(y_1) = f_2(y_2)$. Set $z = f_1(y_1) = f_2(y_2)$. Let $\mathbf{r}_1$ and $\mathbf{r}_2$ be frames which are tangent to S^{n-1} at y_1 and y_2 , respectively, and both are assumed to be positive. Consider the frame

$$\{df_1(\mathbf{r}_1), \mathbf{v}, df_2(\mathbf{r}_2)\}$$

at $z \in STM$ where $\mathbf{v}$ is a vector described in 1.4. We put $\tilde{\sigma}(\rho, t_0) = 1$ if this frame gives us the orientation of STM , otherwise we put $\tilde{\sigma}(\rho, t_0) = -1$.

Because of the transversality and condition (c) from 1.3, the family $\{df_1(\mathbf{r}_1), \mathbf{v}, df_2(\mathbf{r}_2)\}$ is really a frame.

Notice also that the vector $\mathbf{v}$ is not well- defined, but the above defined sign $\tilde{\sigma}$ is.

Clearly if we traverse the path ρ in the opposite direction then the sign of the crossing changes.

2.2. Definition. Suppose that a front W passes through a point $x \in M$ at the moment of time t_0 in such a way that the velocity vector $\mathbf{v}_x$ of the front $W(t_0)$ at x is transverse to $W(t_0)$, $W(t_0)$ restricted to a small neighborhood U of $W^{-1}(t_0)(x)$ is an embedding, and x has only one preimage under $W(t_0)$.

Recall that the manifold M is oriented. Let o_x be the local orientation of $W(t_0)$ at x (i.e. the orientation of the tangent plane T_x to $W(t_0)$). We say that the local orientation o_x is *positive*, and write $\sigma(W(t_0), x) = 1$ if the pair $(o_x, \mathbf{v}_x)$ gives us the orientation of M ; otherwise we say that the local orientation of $W(t)$ at x is *negative* and write $\sigma(W(t_0), x) = -1$.

Notice that the same wave front $W(t)$ can contain two points x and y such o_x is positive orientation while o_y is the negative one, see Figure 1.

Consider a generic pair (P_1, P_2) of propagations $P_1 = (L_1, x_1, V_1, T_1)$ and $P_2 = (L_2, x_2, V_2, T_2)$. **In the rest of Section 2 we assume that $T_1 \leq T_2$. The case where $T_1 > T_2$ is treated in a similar way.**

Let $t > T_2$ be a generic moment of time, i.e. the one at which dangerous intersections do not occur.

Let $c_i, i \in I \subset \mathbb{N}$ where $T_2 < c_i < t$ be moments of time when dangerous intersections did occur.

2.3. Definition. We define $\sigma(W_1(c_i), W_2(c_i))$ as the sign $\tilde{\sigma}$ of the corresponding passage of Σ_0 .

FIGURE 1

Notice that $\sigma(W_1(c_i), W_2(c_i))$ is symmetric if n is even and skew-symmetric if n is odd.

Let $p_j, j \in J \subset \mathbb{N}$ be the moments of time when the front W_1 passed through the point x_2 before the front W_2 originated. (Notice that $p_j < T_2$ and that $\sigma(W_1(p_j), x_2)$ is well-defined since the pair of propagations is generic.) A straightforward verification shows that

$$\sigma(W_1(p_j), x_2) = \tilde{\sigma}(\rho, t_0).$$

where $\rho(t) = (\widetilde{W}_1(t), \varepsilon_{x_2}), t \in (p_j - \delta, p_j + \delta)$.

2.4. Definition. We set

$$\text{CR}(W_1(t), W_2(t)) = \sum_{i \in I} \sigma(W_1(c_i), W_2(c_i)) + \sum_{j \in J} \sigma(W_1(p_j), x_2) \in \mathbb{Z}$$

and call it the *causality relation invariant* for the fronts $W_1(t)$ and $W_2(t)$ at a given moment of time t . (If in fact $T_1 > T_2$, then the second sum should be $\sum_{k \in K} (-1)^{\dim M} \sigma(W_2(q_k), x_1)$, where $q_k, k \in K \subset \mathbb{N}$ are the moments of time when the front W_2 passed through the point x_1 before the front W_1 originated. One can easily verify that $(-1)^{\dim M} \sigma(W_2(q_k), x_1)$ coincides with the sign of the corresponding crossing of Σ_0 by the path $r = (r_1, r_2)$.)

So, if $\text{CR}(W_1(t), W_2(t)) = k \neq 0$ then the sum of the number of baby-intersections and of the number of dangerous intersections is at least $|k|$. This probably could be interpreted as the quantity that measures either how much faster the first front is than the second so that they could become dangerously intersected; or how many times the first front did pass through the source of the second front before the second front originated.

Now we consider an important special case. *If the above pair (P_1, P_2) of propagations is dangerous intersections free, then*

$$\text{CR}(W_1(t), W_2(t)) = \sum_{j \in J} \sigma(W_1(p_j), x_2).$$

We saw examples of such propagations in 1.9, 1.10, 1.11. It is easy to see that in this case $\text{CR}(W_1(t), W_2(t))$ does not depend on t provided $t > T_2$, and thus it is invariant under the propagation. In particular, if $\text{CR}(W_1(t), W_2(t))$ is non-zero, then we know for a fact that the perturbation caused by the first signal has reached the source point of the second signal before the second signal originated. Moreover, if $\text{CR}(W_1(t), W_2(t)) = k \neq 0$, then we can say for sure that the first wave front has passed through the source point of the second front at least $|k|$ times before the second signal originated. (Of course it could be that it did pass more times, because it could have passed $k + l$ times with a positive sign and l times with a negative sign.) Thus, W_1 and W_2 can be thought of as being causally related.

In case $\text{CR}(W_1, W_2) = 0$ we can not make any conclusions on causality relation between W_1 and W_2 , since it could mean that

- 1: neither of the fronts passed through the origin of the other before the other was born, and thus the fronts are not causally related; or
- 2: the earlier-born front did pass through the origin of the other front $2k \neq 0$ times before the other front was born with k of these passages being positive and k of the passages being negative. In this case the fronts are causally related.

However, for some Riemannian metrics g the second situation could not occur, as the following example shows.

2.5. Example (when $\text{CR}(W_1(t), W(t)) = 0$ if and only if the two fronts are causally unrelated). Consider the case of the propagation law given by a complete Riemannian metric, see 1.10, and assume that the propagations $P_1 = (L, x_1, T_1, V_1)$ and $P_2 = (L, x_2, T_2, V_2)$ be such that $V_1(S^{m-1})$ and $V_2(S^{m-1})$ are spheres of the same radius r in $T_{x_1}M$ and $T_{x_2}M$, respectively. As it was discussed in 1.10, in this case dangerous intersection points between the two fronts are the dangerous tangency points and they do not occur during the propagation of W_1 and of W_2 .

Suppose now that M is a manifold of non-positive sectional curvature. Then, by the Hadamard Theorem, see for example [13], the exponential map $\exp_x : T_x M \rightarrow M$ is the universal covering map for every $x \in M$. Thus, the front $W_i(t) : \exp_{x_i}((t - T_i)V) : S^{m-1} \rightarrow M, i = 1, 2$,

is always an immersion, and the local orientation of a wave front passing through every point x is positive. In particular, all the passages of W_1 through x_2 are positive. Thus these passages can not cancel each other in the definition of $\text{CR}(W_1, W_2)$. And we get that for such cases $\text{CR}(W_1, W_2) \neq 0$ if and only if the fronts are causally related.

Propagation laws given by a Riemannian metric of constant sectional curvature with V_1 and V_2 being spheres of unit radius are extremely important in cosmology and they are known as *Friedmann Cosmology models*, see for example [14], [24], [12], [28]. Thus we conclude that for Friedmann cosmology models given by metrics of constant non-positive sectional curvature $\text{CR}(W_1, W_2) \neq 0$ if and only if W_1 and W_2 are causally unrelated.

3. HOMOTOPY PROPERTIES OF MAPS TO STM

3.1. Definition. Given a map $\alpha : S^1 \times S^{n-1} \rightarrow STM$, we say that α is *special* if $\alpha|_{*\times S^{n-1}}$ has the form ε_x for some $x \in M$, see (1.1). Here $*$ $\in S^1$ is the base point.

3.2. Definition. Given an n -dimensional manifold N and a map $\beta : N \rightarrow STM$, we define $d(\beta)$ to be the degree of the map

$$\text{pr} \circ \beta : N \rightarrow M$$

3.3. Lemma. Let $\alpha : S^1 \times S^{n-1} \rightarrow STM$ be a special map. Then there exists a map $\beta : S^n \rightarrow STM$ such that $d(\beta) = d(\alpha)$.

Proof. We regard S^{n-1} as a pointed space. Consider a map $\tilde{\alpha} : S^1 \times S^{n-1} \rightarrow STM$ such that:

- 1: $\tilde{\alpha}|_{*\times S^{n-1}} = \alpha|_{*\times S^{n-1}}$,
- 2: $\tilde{\alpha}|_{S^1 \times *} = \alpha|_{S^1 \times *}$,
- 3: $\tilde{\alpha}|_{t \times S^{n-1}} = \varepsilon|_{\tilde{\alpha}(t \times *)}$.

We regard $S^1 \times S^{n-1}$ as the CW -complex with four cells e^0, e^1, e^{n-1}, e^n , $\dim e^k = k$. It is easy to see that the maps $\tilde{\alpha}$ and α coincide on the $(n-1)$ -skeleton. Thus, the maps α and $\tilde{\alpha}$ (restricted to the n -cell) together yield a map $\beta : S^n \rightarrow STM$. Clearly $d(\tilde{\alpha}) = 0$, and therefore $d(\beta) = d(\alpha)$. $\square$

3.4. Lemma. Suppose that there exists a map $\beta : S^n \rightarrow STM$ with $d(\beta) \neq 0$. Then the Euler class $\chi \in H^n(M)$ of the tangent bundle $TM \rightarrow M$ is zero.

Proof. We set $f = \text{pr} \circ \beta : S^n \rightarrow M$. Clearly, M is closed and $H^n(M) = \mathbb{Z}$ because $d(\beta) \neq 0$. So, again since $d(\beta) \neq 0$, we conclude $f^*\chi \neq 0$

whenever $\chi \neq 0$. Now the result follows because $f^*\chi$ is the obstruction to the lifting of f to STM , while β is such a lifting of f . $\square$

3.5. Lemma. *Let M^n be an oriented manifold and $\beta : S^n \rightarrow STM$ be a map with $d(\beta) \neq 0$, then M is a closed manifold which is a rational homology sphere.*

Proof. We set $f = \text{pr} \circ \beta : S^n \rightarrow M$ and $d = d(\beta)$. Clearly M is closed because $d(\beta) \neq 0$. Let $f_! : H_*(M) \rightarrow H_*(S^n)$ be the transfer map, see e.g. [27, V.2.12]. Since $f_*(f^*y \cap x) = y \cap f_*x$ for all $x \in H_*(S^n)$ and $y \in H^*(M)$, we conclude that $f_*f_!(z) = dz$, for all $z \in H_*(M)$. In particular, since $H_i(S^n) = 0$, for $0 < i < n$, then $dH_i(M) = 0$, for $0 < i < n$. Thus $H_i(M; \mathbb{Q}) = 0$ for $0 < i < n$ and M is a rational homology sphere. $\square$

3.6. Corollary. *If M^{2k} is an even-dimensional oriented manifold, then $d(\beta) = 0$ for every $\beta : S^n \rightarrow STM$.*

Proof. By Lemma 3.5 we get that if $d(\beta) \neq 0$ for some $\beta : S^{2k} \rightarrow STM$, then $H_i(M; \mathbb{Q}) = 0$ for $0 < i < 2k$ and $H_0(M, \mathbb{Q}) = H_{2k}(M, \mathbb{Q}) = \mathbb{Q}$. Thus the Euler characteristic of M is 2 and the Euler class of the tangent bundle $TM \rightarrow M$ is non-zero (in fact, ± 2). This contradicts to the statement of Lemma 3.4. $\square$

Let $\deg : \pi_n(M^n) \rightarrow \mathbb{Z}$ be the degree homomorphism, i.e., the homomorphism which assigns the degree $\deg f$ to the homotopy class of a map $f : S^n \rightarrow M$. (In fact, it coincides with the Hurewicz homomorphism $h : \pi_n(M) \rightarrow H_n(M)$ for M closed and is zero for M non-closed.)

3.7. Definition. Given a connected oriented manifold M^n , we define an Abelian group $\mathbf{A}(M)$ and a homomorphism $q = q_M : \mathbb{Z} \rightarrow \mathbf{A}(M)$ as follows. If n is even, then $\mathbf{A}(M) = \mathbb{Z}$ and $q = 1_{\mathbb{Z}}$. If n is odd, then $\mathbf{A}(M)$ is the cokernel of the degree homomorphism $\deg : \pi_n(M) \rightarrow \mathbb{Z}$ and $q : \mathbb{Z} \rightarrow \mathbf{A}(M)$ is the canonical epimorphism.

3.8. Proposition. *Let M^n be an odd-dimensional manifold as in Definition 3.7. Then the following holds:*

- (i) *If the universal covering space of M is a non-compact manifold, then $\mathbf{A}(M) = \mathbb{Z}$.*
- (ii) *If M admits a complete Riemannian metric of non-positive sectional curvature, then $\mathbf{A}(M) = \mathbb{Z}$.*
- (iii) *If M is not a rational homology sphere, then $\mathbf{A}(M) = \mathbb{Z}$.*
- (iv) *If $\pi_1(M)$ is infinite, then $\mathbf{A}(M) = \mathbb{Z}$.*

(v) If $\pi_1(M)$ is a finite group of order k , then $A(M) = \mathbb{Z}/m\mathbb{Z}$ where $k|m$ (the case $m = 0$. i.e. $A = \mathbb{Z}$ is also possible).

(vi) If M is a closed manifold with $\mathbf{A}(M) = 0$, then M is a homotopy sphere.

Proof. (i) This follows because every map $S^n \rightarrow M$ passes through the universal covering $\widetilde{M} \rightarrow M$ while $H_n(\widetilde{M}) = 0$. Therefore the Hurewicz homomorphism $h : \pi_n(M) \rightarrow H_n(M)$ is trivial.

(ii) The Hadamard Theorem says that the universal covering of such M^n is diffeomorphic to $\mathbb{R}^n$, see for example [13], and the statement follows from (i).

(iii) This follows immediately from Lemma 3.5.

(iv) This follows from (i) since the universal covering space of M is non-compact.

(v) This follows because every map $S^n \rightarrow M$ passes through the universal covering map $p : \widetilde{M} \rightarrow M$ which is of degree k .

(vi) If $\mathbf{A}(M) = 0$ then there exists a map $S^n \rightarrow M$ of degree 1. Since every map of degree 1 induces epimorphism of fundamental groups and homology groups, we conclude that M is a homotopy sphere. $\square$

4. THE AFFINE LINKING INVARIANT AL AS A REDUCTION OF CR

4.1. Definition. We define Σ_1 to be the subset (stratum) of Σ consisting of all the pairs (f_1, f_2) such that there exists precisely two pairs of points $y_1, y_2 \in S^{n-1}$ as in 1.3. Here we assume that the two double points of the image are distinct.

Notice that Σ_i is a stratum of codimension i in Σ . In particular, a generic path in $\mathcal{S} \times \mathcal{S}$ intersects Σ_0 in a finite number of points, and a generic disk in $\mathcal{S} \times \mathcal{S}$ intersects Σ_1 in a finite number of points and does not contain singular mappings that are not in $\Sigma_0 \cup \Sigma_1$.

A generic path $\gamma : [0, 1] \rightarrow \mathcal{S} \times \mathcal{S}$ that connects two points in $\mathcal{S} \times \mathcal{S} \setminus \Sigma$ intersects Σ_0 in finitely many points $\gamma(t_j), j \in J \subset \mathbb{N}$ and all the intersection points are of the types described in 2.1. Put

$$(4.1) \quad \Delta_{\text{AL}}(\gamma) = \sum_{j \in J} \sigma(\gamma, t_j) \in \mathbb{Z}.$$

We let $A = \{(x, y) \in \mathbb{R}^2 \mid x^2 + y^2 \leq 1\}$, $B_1 = \{(x, y) \in A \mid xy = 0\}$, $B_2 = \{(x, y) \in A \mid x = 0\}$, $B_3 = \{(0, 0)\}$, $B_4 = \emptyset$.

We define a *regular disk* in $\mathcal{S} \times \mathcal{S}$ as an embedded disk D such that the triple $(D, D \cap \Sigma_0, D \cap \Sigma_1)$ is homeomorphic to a triple (A, B, C) , $A \supset B \supset C$ where B is one of B_i 's and C is a (possibly empty) subset of B_3 .

4.2. Lemma. *Let β be a generic loop that bounds a regular disk in $\mathcal{S} \times \mathcal{S}$. Then $\Delta_{\text{AL}}(\beta) = 0$.*

Proof. Straightforward. $\square$

4.3. Lemma. *Let β be a generic loop that bounds a disk in $\mathcal{S} \times \mathcal{S}$. Then $\Delta_{\text{AL}}(\beta) = 0$.*

Proof. Without loss of generality we can (using a small deformation of the disk) assume that the disk is the union of regular ones, cf. Arnold [4], [3]. Now the proof follows from Lemma 4.2. $\square$

Notice that $\mathcal{S} \times \mathcal{S}$ is path connected.

4.4. Corollary. *The invariant Δ_{AL} induces a well-defined homomorphism $\Delta_{\text{AL}} : \pi_1(\mathcal{S} \times \mathcal{S}, *) \rightarrow \mathbb{Z}$.*

Proof. Since every element of $\pi_1(\mathcal{S} \times \mathcal{S}, *)$ can be represented by a generic loop, the proof follows from Lemma 4.3. $\square$

Let x_1, x_2 be two distinct points of M . Let $\alpha : S^1 \times S^{n-1} \rightarrow STM$ be a special map (see Definition 3.1) such that the composition

$$S^{n-1} \subset S^1 \times S^{n-1} \xrightarrow{\alpha} STM$$

has the form ε_{x_1} , and let $e : S^1 \times S^{n-1} \rightarrow STM$ be the map of the form

$$S^1 \times S^{n-1} \xrightarrow{\text{proj}} S^{n-1} \xrightarrow{\varepsilon_{x_2}} STM$$

Then (α, e) is a loop in $(\mathcal{S} \times \mathcal{S}, *)$.

4.5. Lemma. $\Delta_{\text{AL}}[(\alpha, e)] = d(\alpha)$.

Proof. Notice that $\Delta_{\text{AL}}[(\alpha, e)]$ is the intersection index of the cycles $\alpha(S^1 \times S^{n-1})$ and $S_{x_2}^{n-1}$. This index coincides with the degree of the map $\text{pr} \circ \alpha$ because the last one is equal to the algebraic number of the preimages of x_2 . $\square$

4.6. Definition. Take two different points $x_1, x_2 \in M$ and consider the point $* = (\varepsilon_{x_1}, \varepsilon_{x_2}) \in \mathcal{S} \times \mathcal{S} \setminus \Sigma$, take an arbitrary point $f = (f_1^1, f_2^1) \in \mathcal{S} \times \mathcal{S} \setminus \Sigma$ and choose a generic path γ going from $*$ to f . We set

$$\text{AL}(f) = q(\Delta_{\text{AL}}(\gamma)) \in \mathbf{A}(M)$$

and call AL the *affine linking invariant*. Here q is the epimorphism from Definition 3.7.

4.7. Theorem. *The function $\text{AL} : \pi_0(\mathcal{S} \times \mathcal{S} \setminus \Sigma) \rightarrow \mathbf{A}(M)$ is well-defined and increases by $1 \in \mathbf{A}(M)$ under the positive transverse passage through the stratum Σ_0 .*

4.8. Remark. It is easy to see that AL does not depend on the choice of the pair (x_1, x_2) used to define it. This follows, since all the pairs $(\varepsilon_{x_1}, \varepsilon_{x_2}), x_1, x_2 \in M$ are isotopic.

However, if one chooses a basepoint $\tilde{*}$ in the construction of AL that is not two fibers over two distinct points, then the AL-type invariant obtained this way would be different from AL by an additive constant $\text{AL}(\tilde{*}) - \text{AL}(*).$ This ambiguity is similar to the ambiguity in the choice of the zero vector in an affine vector space, and it is the reason for the adjective “affine” in the name of the invariants. The general theory of affine linking invariants is discussed in our work [10].

Proof of Theorem 4.7. To show that AL is well-defined we must verify that the definition is independent on the choice of the path γ that goes from $*$ to f . This is the same as to show that $q(\Delta_{\text{AL}}(\varphi)) = 0$ for every closed generic loop φ at $*$.

Since $\Delta_{\text{AL}} : \pi_1(\mathcal{S} \times \mathcal{S}, *) \rightarrow \mathbb{Z}$ is a homomorphism, it suffices to prove that $q(\Delta_{\text{AL}}(\varphi)) = 0$ for all generators φ of $\pi_1(\mathcal{S} \times \mathcal{S}, *)$.

The classes $[(\alpha, e)]$ and similar classes $[(e, \alpha)]$ generate the group $\pi_1(\mathcal{S} \times \mathcal{S}, *)$. By Lemma 4.5 we have

$$\Delta_{\text{AL}}[(\alpha, e)] = d(\alpha).$$

Clearly, $d(\alpha) = 0$ if M is an non-closed manifold. So, we assume M to be closed. Now, for n even $d(\alpha) = 0$ by Corollary 3.6, while for n odd $q(d(\alpha)) = 0$ by Lemma 3.3. $\square$

Let (P_1, P_2) be a generic pair of propagations, and let t be a moment of time when dangerous intersection do not occur. Let $q : \mathbb{Z} \rightarrow \mathbf{A}(M)$ be the epimorphism described in Definition 3.7.

4.9. Theorem. *The invariants CR and AL are related as follows:*

$$q(\text{CR}(W_1(t), W_2(t))) = \text{AL}(\widetilde{W}_1(t), \widetilde{W}_2(t)).$$

Proof. The Theorem follows because the signs defined for dangerous intersections (as well as for baby-intersections) are exactly the sign of the corresponding crossings of Σ_0 . $\square$

The invariant AL works especially nice for even dimensional manifolds, since in these cases $\mathbf{A}(M) = \mathbb{Z}$.

If the pair of propagations is dangerous intersections free then the invariant $\text{AL}(\widetilde{W}_1(t), \widetilde{W}_2(t)) \in \mathbf{A}$ gives us the number of times the earlier-born front had passed through the birth point of the other front before the other front was born. It is also easy to see that if the other wave front did not appear yet, then $\text{AL}(\widetilde{W}_1(t), \widetilde{W}_2(t))$ is the number of times

the earlier-born front passed through the (future) birth point of the other front by the time moment t .

We illustrate our general results with the following example.

4.10. Theorem. *Assume that the law of propagation L is given by a complete Riemannian metric as in 1.10, of non-positive sectional curvature on M and the wave fronts $W_i(t)$, $i = 1, 2$, correspond respectively to propagations $P_i = (L, x_i, T_i, V_i)$, $i = 1, 2$, with $V_i : S^{n-1} \rightarrow T_{x_i}M$, $i = 1, 2$, being spheres of the same radius. Then W_1 and W_2 are causally related if and only $\text{AL}(\widetilde{W}_1(t), \widetilde{W}_2(t)) \neq 0$.*

Proof. As it was explained in 2.5 for such propagations $\text{CR}(W_1, W_2) \neq 0$ if and only if W_1 and W_2 are causally related. Notice that $\mathbf{A}(M) = \mathbb{Z}$ if M is even-dimensional by definition of $\mathbf{A}(M)$, while $\mathbf{A}(M) = \mathbb{Z}$ for M odd-dimensional by Proposition 3.8. Now the result follows from Theorem 4.9. $\square$

This Theorem, in particular, says that $\text{AL}(W_1(t), W_2(t))$ allows one to detect always whether W_1 and W_2 are causally related or not in Friedmann models based on metrics of constant non-positive sectional curvature.

5. CAUSALITY RELATION INVARIANT IN THE CASE OF THE PROPAGATION ACCORDING TO RIEMANNIAN METRICS.

As it was noticed in 1.10, if a propagation happens according to a complete Riemannian metric and $\text{Im } V$ is a sphere, then the velocities of the points of the front are always orthogonal to the front. So, if each of the two propagations happens according to a complete Riemannian metric, then dangerous tangency points and the dangerous intersection points are the same thing. In this section we deal only with this case. Namely, we provide an explicit way of calculation of the invariant CR . We need some preliminaries.

Let W be a wave front, and let $x \in \text{Im } W(t)$ be a non-singular point of $W(t)$. For sake of simplicity we denote $T_x(\text{Im } W(t))$ just by T . Let O be a small neighborhood of x in M , and let $U = O \cap \text{Im } W(t)$. Without loss of generality we can and shall assume that the injectivity radius is big enough (≥ 3) for all points of O .

The Riemannian metric g on M produces a unique symmetric connection on M . So, for every $a \in O$, the parallel transport along the geodesic segment (connecting x and a) gives us an isomorphism

$$(5.1) \quad \tau_a : T_a M \rightarrow T_x M$$

Furthermore, we can regard every sphere $S_a \in STM, a \in M$ as the unit sphere in $T_a M$, and so STM can be regarded as the total space of the unit sphere subbundle of TM . Since the connection respects the Riemannian metric, we conclude that $\tau_a(S_a) = S_x$.

5.1. Definition. (a) We define

$$\pi : \text{pr}^{-1}(O) \rightarrow S_x$$

as follows. A point $z \in \text{pr}^{-1}(O)$ is a pair (a, ξ) with $a = \text{pr}(z)$ and $\xi \in S_a$, and we set $\pi(z) = \tau_a(\xi)$ with τ_a as in (5.1).

(b) Let $\mathbf{n}_u$ be the unit normal vector to U at u that points to the direction of propagation of the front. We define the Gauss map $G = G_W : U \rightarrow S_x$ by setting $G(u) = \tau_u(\mathbf{n}_u)$.

(c) Given $u \in U$, let $\ell(u) = \mathbf{n}_u \in \text{Im } \widetilde{W}$. In this way we get a map $\ell : U \rightarrow \text{Im } \widetilde{W} \subset STM$. We set $z = \ell(x)$. Given $\mathbf{e} \in T$, we set

$$\mathbf{e}^W := d\ell(\mathbf{e}), \quad \mathbf{e}^W \in T_z \text{Im } \widetilde{W} \subset T_z STM.$$

It is clear that $d\ell : T \rightarrow T_z \text{Im } \widetilde{W}$ is an isomorphism.

(d) Let $z \in STM$ be the point described in (c). We define the horizontal section $H : O \rightarrow STM$ of pr by setting

$$H(a) = \tau_a^{-1}(z) \in S_a \subset STM.$$

Furthermore, given $\mathbf{w} \in T_a M, a \in O$, we set

$$\mathbf{w}^H = dH(\mathbf{w}) \in T_{H(a)} STM.$$

Clearly, $\mathbf{w}^H$ can be characterized by the properties

$$(d\text{pr})(\mathbf{w}^H) = \mathbf{w}, \quad d\pi(\mathbf{w}^H) = \mathbf{0}.$$

(e) Let $z \in STM$ be the point described in (c). Given $\mathbf{w} \in T_x M$, we define $\mathbf{w}^S \in T_z T_x M$ as follows. We regard z as the vector $\mathbf{z} \in T_x M$. Furthermore, we regard $T_x M$ as the affine space T^{aff} over the vector space $T_x M$ and consider the parallel shift

$$P_{\mathbf{z}} : T^{\text{aff}} \rightarrow T^{\text{aff}}, \quad a \mapsto a + \mathbf{z}.$$

Let $o \in T^{\text{aff}}$ correspond to the origin of the vector space $T_x M$. Using the obvious identification $T_x M = T_o T^{\text{aff}}$, we regard $\mathbf{w}$ as the tangent vector $\mathbf{w}_o \in T_o T^{\text{aff}}$, and we set

$$\mathbf{w}^S = dP_{\mathbf{z}}(\mathbf{w}_o) \in T_z T^{\text{aff}} = T_z T_x M.$$

Notice that if $\mathbf{e} \in T$ then $\mathbf{e}^S \in T_z S_x$. (This is where the notation comes from: $\mathbf{e}^S$ is the spherical lifting of $\mathbf{e}$.)

5.2. Lemma. For every $\mathbf{e} \in T$ we have $\mathbf{e}^W - \mathbf{e}^H = dG(\mathbf{e})$.

Proof. First, notice that $G = \pi \circ \ell : U \rightarrow S_x$. So, $d\pi(\mathbf{e}^W) = dG(\mathbf{e})$. Now,

$$(d\pi)(\mathbf{e}^W - dG(\mathbf{e})) = \mathbf{e} - \mathbf{0} = \mathbf{e}$$

and

$$d\pi(\mathbf{e}^W - dG(\mathbf{e})) = dG(\mathbf{e}) - dG(\mathbf{e}) = \mathbf{0}.$$

Thus, $\mathbf{e}^W - dG(\mathbf{e}) = \mathbf{e}^H$. $\square$

5.3. Proposition. *Let $\mathbf{e} \in T$, and let $\mathbf{n}$ be the normal vector field to U in M . Then $dG(\mathbf{e}) = (\nabla_{\mathbf{e}}\mathbf{n})^S$.*

Here ∇ denotes the covariant differentiation operation on M .

Proof. Let $\gamma : (-\delta, \delta) \rightarrow U$ be a curve with $\dot{\gamma}(0) = \mathbf{e}$. We define the curve $\zeta : (-\delta, \delta) \rightarrow S_x$ by setting $\zeta(t)$ to be the end of the vector $\tau_{\gamma(t)}\mathbf{n}_{\gamma(t)}$. Since

$$\nabla_{\mathbf{e}}\mathbf{n} = \frac{d}{dt} (\tau_{\gamma(t)}\mathbf{n}_{\gamma(t)} - \mathbf{n}_x) \Big|_{t=0}$$

we conclude that $\dot{\zeta}(0) = (\nabla_{\mathbf{e}}\mathbf{n})^S$. On the other hand, $G \circ \gamma = \zeta$, and thus

$$dG(\mathbf{e}) = dG(\dot{\gamma}(0)) = (G \circ \gamma)'(0) = \dot{\zeta}(0) = (\nabla_{\mathbf{e}}\mathbf{n})^S. \quad \square$$

5.4. Corollary. $\mathbf{e}^W - \mathbf{e}^H = (\nabla_{\mathbf{e}}\mathbf{n})^S$.

Proof. This is the direct consequence of 5.2 and 5.3. $\square$

Consider the Weingarten operator

$$(5.2) \quad A = A_W : T \rightarrow T, \quad A(\mathbf{e}) = \nabla_{\mathbf{e}}\mathbf{n}.$$

The Corollary 5.4 can now be written as follows:

$$(5.3) \quad \mathbf{e}^W - \mathbf{e}^H = (A\mathbf{e})^S.$$

Now let W_1 and W_2 be two wave fronts, and let $x \in M$ be a point of dangerous tangency of $W_1(t)$ and $W_2(t)$. We assume that the corresponding pair of propagations is generic. Again, we denote by T the common tangent plane $T_x W_i(t), i = 1, 2$. Let $A_i := A_{W_i} : T \rightarrow T, i = 1, 2$ be the Weingarten operators considered in (5.2). We set $B = A_1 - A_2$. It is well known that each A_i is a self-adjoint operator, [29, Ch. 7], and therefore B is. Let $k_1, \dots, k_{n-1}$ be the eigenvalues (with multiplicities) of B .

5.5. Proposition. $\text{Ker } B = 0$, and so $k_i \neq 0$ for all i .

Proof. Let $\mathbf{e} \neq \mathbf{0}$ be a vector with $B\mathbf{e} = \mathbf{0}$. Then

$$\mathbf{e}^{W_1} - \mathbf{e}^{W_2} = (\mathbf{e}^{W_1} - \mathbf{e}^H) - (\mathbf{e}^{W_2} - \mathbf{e}^H) = (A_1\mathbf{e} - A_2\mathbf{e})^S = (B\mathbf{e})^S = \mathbf{0}.$$

i.e. $T_x \text{Im } \widetilde{W}_1 \cap T_x \text{Im } \widetilde{W}_2 \neq \mathbf{0}$. But this is impossible because the pair of propagations is assumed to be generic (see conditions 1.6(b) and 1.3(c)). $\square$

In particular, $\det B = k_1 \cdots k_{n-1} \neq 0$.

5.6. Definition (Alternative definition of $\sigma(W_1(t), W_2(t))$). We put $\varepsilon(W_1(t), W_2(t)) = 1$ if both fronts have the same local orientations at x (as defined in 2.2) and $\varepsilon(W_1(t), W_2(t)) = -1$ if the fronts have opposite local orientations. Now we set

$$\widehat{\sigma}(W_1(t), W_2(t)) = \varepsilon(W_1(t), W_2(t)) \text{sign}(\det B) \text{sign}(|\mathbf{v}_1| - |\mathbf{v}_2|)$$

where $\mathbf{v}_i$ is the velocity vector of $W_i(t)$ at x .

5.7. Theorem. $\widehat{\sigma}(W_1(t), W_2(t)) = \sigma(W_1(t), W_2(t))$.

Proof. Given a vector $\mathbf{e} \in T$, we set $\mathbf{e}' = \mathbf{e}^{W_1}$ and $\mathbf{e}'' = \mathbf{e}^{W_2}$. Choose a basis $\{\mathbf{e}_1, \dots, \mathbf{e}_{n-1}\}$ of T containing of the eigenvectors of B , i.e., $B\mathbf{e}_i = k_i\mathbf{e}_i$. Because of equality (5.3) we have

$$(5.4) \quad \mathbf{e}_i'' - \mathbf{e}_i' = (B\mathbf{e}_i)^S = (k_i\mathbf{e}_i)^S = k_i\mathbf{e}_i^S.$$

We can and shall assume that the frame $\{\mathbf{e}_1, \dots, \mathbf{e}_{n-1}\}$ gives the positive (local) orientation of $W_i(t), i = 1, 2$ at x . Take the polyvector

$$\mathbf{p} := \mathbf{e}_1' \wedge \cdots \wedge \mathbf{e}_{n-1}' \wedge \mathbf{v} \wedge \mathbf{e}_1'' \wedge \cdots \wedge \mathbf{e}_{n-1}''$$

where $\mathbf{v}$ is the vector defined in 1.4. Then $\mathbf{p} \neq 0$ since the pair of propagations is assumed to be generic. Notice that $\mathbf{p}$ gives us an orientation of STM , and we say that $\mathbf{p}$ is positive if this orientation coincides with the original one, otherwise we say that $\mathbf{p}$ is negative.

According to Definition 2.3, the sign of $\mathbf{p}$ is equal to

$$\varepsilon(W_1(t), W_2(t))\sigma(W_1(t), W_2(t)).$$

So, we must prove that sign of the polyvector $\mathbf{p}$ is equal to the sign of

$$(\det B) \text{sign}(|\mathbf{v}_1| - |\mathbf{v}_2|).$$

To be definite, we assume that $|\mathbf{v}_1| > |\mathbf{v}_2|$ and prove that the sign of $\mathbf{p}$ is equal to the sign of $\det B$.

Since $\mathbf{e}_i'' = \mathbf{e}_i' + k_i\mathbf{e}_i^S$ and $\det B = k_1 \cdots k_{n-1}$, we conclude that

$$\mathbf{e}_1' \wedge \cdots \wedge \mathbf{e}_{n-1}' \wedge \mathbf{v} \wedge \mathbf{e}_1'' \wedge \cdots \wedge \mathbf{e}_{n-1}'' = (\det B) \mathbf{e}_1' \wedge \cdots \wedge \mathbf{e}_{n-1}' \wedge \mathbf{v} \wedge \mathbf{e}_1^S \wedge \cdots \wedge \mathbf{e}_{n-1}^S.$$

So, it remains to prove that the polyvector

$$\mathbf{e}_1' \wedge \cdots \wedge \mathbf{e}_{n-1}' \wedge \mathbf{v} \wedge \mathbf{e}_1^S \wedge \cdots \wedge \mathbf{e}_{n-1}^S$$

is positive.

Since $\mathbf{e}'_1 \wedge \cdots \wedge \mathbf{e}'_{n-1} \wedge \mathbf{v} \wedge \mathbf{e}_1^S \wedge \cdots \wedge \mathbf{e}_{n-1}^S \neq 0$, we conclude that the family $\{\mathbf{e}_1^S, \dots, \mathbf{e}_{n-1}^S\}$ generate $T_z S_x$. It is easy to see that the frame $\{\mathbf{e}_1^S, \dots, \mathbf{e}_{n-1}^S\}$ gives the original orientation of S_x , since the frame $\{\mathbf{e}_1, \dots, \mathbf{e}_{n-1}\}$ gives the positive local orientation of each of the fronts at x . So, it remains to prove that the polyvector

$$(d \operatorname{pr})(\mathbf{e}'_1 \wedge \cdots \wedge \mathbf{e}'_{n-1} \wedge \mathbf{v}) = \mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_{n-1} \wedge (d \operatorname{pr})\mathbf{v}$$

is positive, i.e. that it gives the original orientation of M . Recall that the polyvector

$$\mathbf{e}_1 \wedge \cdots \wedge \mathbf{e}_{n-1} \wedge (\mathbf{v}_1 - \mathbf{v}_2)$$

is positive since $|\mathbf{v}_1| > |\mathbf{v}_2|$. Taking into account that the vector $\mathbf{v}_1 - \mathbf{v}_2$ is orthogonal to T and points into the direction of both propagations at x , it suffices to prove that $\langle \mathbf{v}_1 - \mathbf{v}_2, (d \operatorname{pr})(\mathbf{v}) \rangle > 0$. But this is clear because W_1 is faster than W_2 at (x, t) , and so the point $\operatorname{pr}(z_1)$ (in notation of 1.4) is further than the point $\operatorname{pr}(z_2)$ from T . $\square$

The following Proposition 5.8 is useful, when calculating $\operatorname{sign} \det B$. Let $\bar{g}$ be another Riemannian metric. Now we define $\bar{H}, \bar{\pi}, \bar{\ell}, \bar{z}$ and $\bar{G}$ as in 5.1 with respect to the metric $\bar{g}$. We also assume that $\bar{\ell}_1(U_1) \cap \bar{\ell}_2(U_2) = \bar{z}$. Note that in this case the image of $\bar{\ell}$ does not lie in $\operatorname{Im} \bar{W}$, but we can still define the operator $B = B(\bar{g})$ as it is done before Proposition 5.5. We say that a metric $\bar{g}$ is *generic* if $d(\bar{\ell}_1)T_x \operatorname{Im} W_1 \cap d(\bar{\ell}_2)T_x \operatorname{Im} W_2 = 0$.

5.8. Proposition. *If the metric $\bar{g}$ is generic, then $\det B(\bar{g}) \neq 0$ and $\operatorname{sign} \det B(\bar{g}) = \operatorname{sign} \det B(g)$.*

5.9. Remark. Probably the most useful case of this proposition is when $\bar{g}$ is chosen to be locally flat in the neighborhood of the dangerous tangency point and so that one of the fronts is (locally) a totally geodesic submanifold.

Proof of Proposition 5.8. First, notice that the set of all Riemannian metrics is path connected because it is convex. Second, notice that $\det B(\hat{g}) \neq 0$ for every generic metric $\hat{g}$. (This is proved in the same way as Proposition 5.5.) Furthermore, the set of non-generic metrics has codimension > 1 in the space of all metrics. So, there exists a continuous family $g_t, t \in [0, 1]$, of Riemannian metrics such $g_0 = g, g_1 = \bar{g}$ and each g_t is generic. Clearly, $B(g_t)$ depends on t continuously and $\det B(g_t) \neq 0$ since g_t is generic. Thus the sign of $\det B(g_t)$ is the same for all t . $\square$

FIGURE 2

5.10. **Example** (of calculation of $\sigma(\widetilde{W}_1(t), \widetilde{W}_2(t))$). Suppose that the fronts propagate as it is shown in Figure 2.

Let W_1 be the “right” front. Then, clearly,

$$\sigma(W_1(t), W_2(t)) = -\varepsilon(W_1(t), W_2(t)).$$

The negative sign appears because W_2 is faster than W_1 .

6. EXAMPLES

To illustrate the usage of the affine linking invariant consider the following examples.

6.1. **Example.** Here we show how to apply AL to determining the causality relation. Let M be a smooth oriented n -dimensional manifold that is not an odd-dimensional homotopy sphere. Let W_1, W_2 be the wave fronts that originated on M long time ago and were propagating according to the dangerous intersections free pair of propagations $\{P_1, P_2\}$.

Assume that the current picture of wave fronts $W_1(t), W_2(t)$ is the one shown in Figure 3 with the velocity vectors normal to the two spheres shown in Figure 3. (Note that after the contracting front contracts to a point it does not appear but rather everts and turns into an expanding spherical front.)

Then a straightforward calculation shows that $\text{AL}(\widetilde{W}_1(t), \widetilde{W}_2(t)) - \text{AL}(V_1, V_2) = \pm 1 \neq 0$ (we used the notation as in Theorem 4.9), and thus the first wave front reached the birth point of the second front before the second front originated. (The sign of ± 1 in this example depends on which of the two fronts shown in Figure 3 is W_1 in the case where n is odd and is always a plus sign when n is even.)

This seems to demonstrate that AL is a very powerful invariant because in this case we know neither the propagation laws nor when and where the fronts originated. In fact, in this example we can make this

FIGURE 3

conclusion even without the knowledge of the topology of M outside of the depicted part of it.

6.2. Example. Here we show how to apply AL to estimating of the number of times the wave front passed through a given point between the two moments of time.

Assume that we have a wave front W that propagates on M and that M is not an odd-dimensional homotopy sphere.

Assume that at a certain moment of time the picture of the wave front was the one shown in Figure 4.a and later it developed into the shape shown in Figure 4.b. (The Figure 4.b depicts a sphere that can be obtained from the trivially embedded sphere by passing three times through a point and by creation of some singularities far away from x .)

FIGURE 4

Let $\widetilde{W}(t_1), \widetilde{W}(t_2) : S^{n-1} \rightarrow STM$ be the liftings of the fronts shown in Figure 4.a and b respectively. A straightforward calculation shows

that $\text{AL}(\widetilde{W}(t_2), \varepsilon_x) - \text{AL}(\widetilde{W}(t_1), \varepsilon_x) = 3 \in \mathbf{A}(M)$ for every map $\varepsilon_x : S^{n-1} \rightarrow STM$ as in (1.1).

Thus if the dimension of the ambient manifold is even, or if $\pi_1(M)$ is infinite, then (see 3.8) W did pass at least three times through the point x between the time moments shown in Figure 4.a and 4 b. Once again, this conclusion does not depend on the topology of M outside of the part of it depicted in Figure 4, on the time passed between the two pictures taken, and on the propagation law.
